Abstract: We study extensions of the $k$-SUM problem to vector spaces over finite fields. Given a subset $S \subseteq \mathbb{F}_q^d$ of size $r \leq q^n$, an integer $k$, $2 \leq k \leq n$, and a vector $v \in (\mathbb{F}_q^k \setminus \{0\})^k$, we define the TARGETSUM problem to be the problem of finding $k$ elements $x_{i_1}, \ldots, x_{i_k} \in S$ for which $\sum_{j=1}^k v_j x_{i_j} = z$, where $z$ may either be an input or a fixed vector. We also study a variant of this, where instead of finding $x_{i_1}, \ldots, x_{i_k} \in S$ for which $\sum_{j=1}^k v_j x_{i_j} = z$, we require that $z$ be in $\text{span}(x_{i_1}, \ldots, x_{i_k})$, which we call the $(k, r)$-LINDEPENDENCE$_q$ problem.

These problems are natural generalizations of well-studied problems that occur in coding theory and property testing. Indeed, the $(k, r)$-LINDEPENDENCE$_q$ problem is just the MAXIMUM LIKELIHOOD DECODING problem for linear codes. Also, in the TARGETSUM problem, if instead of general $z$ we require $z = 0^n$, then this is the WEIGHT DISTRIBUTION problem for linear codes. In property testing, these problems have been implicitly studied in the context of testing linear-invariant properties.

We give nearly optimal bounds for TARGETSUM and $(k, r)$-LINDEPENDENCE$_q$ for every $r, k$, and constant $q$. Namely, assuming 3-SAT requires exponential time, we show that any algorithm for these problems must run in $\min(2^{\Theta(n)}, r^{\Theta(k)})$ time. Moreover, we give deterministic upper bounds that match this complexity, up to constant factors in the exponent. Our lower bound strengthens and simplifies an earlier $\min(2^{\Theta(n)}, r^{\Omega(k^{1/4})})$ lower bound for both the MAXIMUM LIKELIHOOD DECODING and WEIGHT DISTRIBUTION problems.

We also give upper and lower bounds for variants of these problems, e.g., for the problem for which we must find $x_{i_1}, \ldots, x_{i_k}$ for which $z \in \text{span}(x_{i_1}, \ldots, x_{i_k})$ but $z$ is not spanned by any proper subset of these vectors, and for the counting version of this problem.

Keywords: Coding theory; Computational Geometry, $k$-Sum

1 Introduction

We study the computational complexity of algorithms that test if linear combinations of certain-sized subsets of a set of input vectors equal a desired target vector. This is a fundamental problem with applications to coding theory, computational geometry, and property testing.

The special case when the field is $\mathbb{R}$, there is only a single dimension, and one wants to find a sum of $k$ numbers that equals 0 is the well-known $k$-SUM problem. Many problems, especially in computational geometry, have been shown to be $k$-SUM hard for certain $k$; see, for example, the works of [20–22, 25, 38, 40]. Some problems known to be 3-SUM hard include 3-POINTS-ON-LINE, MINIMUM-AREA-TRIANGLE, SEPARATOR,

1 STRIPS-COVER-BOX, TRIANGLES-COVER-TRIANGLE, PLANAR-MOTION-PLANNING, DIHEDRAL-ROTATION, and POLYGON-CONTAINMENT; see the survey by King [31]. As stated in [5], the body of work on 3-SUM “is perhaps the most successful attempt at understanding the complexity inside $\mathcal{P}$ (polynomial time).” We believe the study of the extension of this problem to vector spaces over finite fields will likewise result in a deeper understanding of the complexity of many other problems.

Let $\mathbb{F} = \mathbb{F}_q$ be the finite field of $q$ elements and let $n$ be a natural number. We assume that $q$ is a constant independent of $n$. The main problems we study are the following.

Let $k, r : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ be functions.

Definition 1 The $(k, r)$-ZEROSUM$_q$ problem takes as input $r(n)$ many elements $x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n$ and checks if
there exist \(x_1, \ldots, x_{i_1}(n)\) such that \(i_1, \ldots, i_k(n) \in [r(n)]\) and \(x_1 + \cdots + x_{i_k} = 0\).

The \((k, r)\)-TARGETSUM_q problem takes as input \(r(n)\) elements \(x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n\) and checks if there exist \(x_1, \ldots, x_{i_k(n)}\) such that \(i_1, \ldots, i_k(n) \in [r(n)]\) and \(x_1 + \cdots + x_{i_k(n)} = z\).

We also study the following slight extension to general linear combinations of input vectors. Let \(v = (v_1, \ldots, v_{k(n)}) \in (\mathbb{F}_q \setminus \{0\})^{k(n)}\) be a family of vectors.

**Definition 2** For every \(n \geq 1\), the \((k, r, v)\)-ZEROSETSUM_q problem takes as input \(r(n)\) elements \(x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n\) and checks if there exist \(x_1, \ldots, x_k\) such that \(i_1, \ldots, i_k \in [r(n)]\) and \(v_1 x_1 + \cdots + v_k x_k = 0\).

For every \(n \geq 1\), the \((k, r, v)\)-TARGETSUM_q problem takes as input \(r(n)\) elements \(x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n\) and checks if there exist \(x_1, \ldots, x_k\) such that \(i_1, \ldots, i_k \in [r(n)]\) and \(v_1 x_1 + \cdots + v_k x_k = z\).

Notice that for \(q = 2\), \((k, r, v)\)-ZEROSETSUM_q and \((k, r, v)\)-TARGETSUM_q coincide with \((k, r)\)-ZEROSETSUM_q and \((k, r)\)-TARGETSUM_q, respectively. We also consider a related problem when it is more useful to look at the span of vectors than it is to fix a single combination \(v\).

**Definition 3** The \((k, r)\)-LINDEPENSION_q problem takes as input \(r\) elements \(x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n\) and \(z \in \mathbb{F}_q^n\) and checks if there exist \(x_1, \ldots, x_{i_k(n)}\) such that \(z \in \text{span}(x_1, \ldots, x_{i_k(n)})\).

Finally, we consider a variant of this problem which requires the linear dependence to be minimal. Vectors \(x_1, \ldots, x_k\) are said to be minimally linearly dependent if \(0 \in \text{span}(x_1, \ldots, x_k)\), but 0 cannot be written as a non-trivial linear combination of any proper subset of \(\{x_1, \ldots, x_k\}\).

**Definition 4** The \((k, r)\)-MINLINDEPENSION_q problem takes as input \(r(n)\) elements \(x_1, \ldots, x_{r(n)} \in \mathbb{F}_q^n\) and checks if there exist \(x_1, \ldots, x_{i_k(n)}\) that are minimally linearly dependent.

Notice that in all of the above problems, we do not require the \(i_1, \ldots, i_k\) in the solution to be distinct. To understand how these problems are related to existing coding-theoretic problems, consider first the \((k, r)\)-LINDEPENSION_q problem. This is just the

**Maximum Likelihood Decoding problem for linear codes**, that is, the problem of determining the most likely transmitted codeword given a certain received word. This problem is well-studied [6, 18, 19, 23, 28, 42, 46]. To see the connection, if the columns of an \(n \times r\) matrix with elements \(x_1, \ldots, x_{r(n)}\), and the received word is \(z\), then if there are \(k(n)\) elements \(x_1, \ldots, x_{k(n)}\) whose span contains \(z\), then there is a codeword that if corrupted in at most \(k(n)\) positions, equals \(z\).

Now consider the \((k, r)\)-ZEROSETSUM_q problem. Let \(A\) be the \(n \times r\) matrix whose columns correspond to the input vectors to this problem. Consider the code \(C = \{x \in \{0, 1\}^r \: Ax = 0\}\). Then \(C\) is of dimension at least \(r - n\), and the \((k, r)\)-ZEROSETSUM_q problem has a solution iff there is a codeword of weight \(k\). This is the WEIGHT DISTRIBUTION problem for linear codes in coding theory, a problem studied in [6, 18].

In the property testing literature, these problems have been studied in the context of testing linear-invariant properties [30], though the model differs from ours in the sense that the input set is promised to either contain a linear dependence or to be far from a set that does. In analogy to triangles in graphs, we define the triangles in a set \(S \subseteq \mathbb{F}_q^n\) as the triples \((x_1, x_2, x_3)\) such that \(x_1 + x_2 + x_3 = 0\). Similarly, for \(k \geq 3\) we define the \(k\)-cycles [7] in a set \(S \subseteq \mathbb{F}_q^n\) to be the \(k\)-tuples \((x_1, x_2, \ldots, x_k)\) such that each \(x_i \in S\) for \(i = 1, 2, \ldots, k\) and \(x_1 + x_2 + \cdots + x_k = 0\). Green [27] showed that for constant \(k\), one can distinguish, in constant time, between the case when the input set is free from \(k\)-cycles and the case when a constant fraction of the elements of the set need to be removed in order to make it free. This result has been generalized in several directions [7, 8, 32, 33, 44]. In particular, Shapira [44] and Král’, Serra and Vena [32] independently showed that testing whether a set \(S\) is free from containing tuples \(x = (x_1, \ldots, x_k) \in S^k\) satisfying \(M x = b\) (where \(M\) is a constant-sized matrix over \(\mathbb{F}_q\) with \(k\) columns and \(b\) is a vector over \(\mathbb{F}_q^n\)), or whether \(S\) is far from being such a set, can also be done in constant time. Our work can be viewed as addressing the classical versions of these problems.

The problems we study are also similar to those of finding subgraphs inside of graphs. For example, finding solutions to \(x_1 + x_2 + \cdots + x_k = 0\) in a set \(S \subseteq \mathbb{F}_q^n\) and finding \(k\)-cliques in a graph both require finding \(k\) items from the input (elements and vertices, respectively) that satisfy a given constraint. There has been a lot of algorithmic work on the problem of finding subgraphs [1–4, 15, 26, 43, 47, 48]. The best known algorithm for finding triangles [4] runs in time \(O(\min\{|E|^{1/(2w+1)}, n^2\})\), where \(\omega\) is the matrix multiplication exponent, and the best known algorithm for finding \(k\)-cliques in a graph
with \( n \) vertices, due to Nešetřil and Poljak [39], runs in time \( O(n^{792k}) \). It is not known whether algorithms for either of these problems running in time \( O(n^k) \) can be ruled out, although an algorithm for \( k \)-clique running in time \( n^{o(k)} \) would imply a subexponential algorithm for 3-SAT [11, 49]. In contrast, we show that the situation for our linear algebraic problems is much clearer. We can show nearly tight upper and lower bounds based on standard complexity assumptions. Additionally, our upper bounds are relatively stronger, essentially because, while the graph algorithms use fast matrix multiplication which runs in time \( n^{2+0.376} \), for two \( n \)-by-\( n \) matrices, we can use fast convolution which runs in time \( N^{1+o(1)} \) for two real-valued functions over a finite field of order \( N \).

1.1 Results

Assuming 3-SAT cannot be solved in sub-exponential time, we resolve (up to polynomial factors) the time complexity of the problems:

- \((k, r)\)-ZERO SUM
- \((k, r)\)-TARGET SUM
- \((k, r, v)\)-ZERO SUM
- \((k, r, v)\)-TARGET SUM
- \((k, r)\)-LINE INDEPENDENCE

problems. Namely, we show that any deterministic algorithm must run in \( \min(r^{\Theta(k)}, 2^{\Theta(n)}) \) time, and we give a deterministic algorithm running in this amount of time to solve these problems. Our lower bound also holds for randomized algorithms, provided we assume that 3-SAT cannot be solved in sub-exponential time by a randomized algorithm. The complexity assumption we use is the well-known Exponential Time Hypothesis conjectured by Impagliazzo, Paturi, and Zane [29], and used in a number of papers to establish hardness results [12, 13, 24, 34–36]. It is known that this assumption is equivalent to the assumption that \( d \)-SAT cannot be solved in sub-exponential time for some constant \( d \geq 3 \).

Our lower bound strengthens and simplifies the previous lower bound for both the MAXIMUM LIKELIHOOD DECODING and WEIGHT DISTRIBUTION problems [18]. In that paper, the authors start with the INDEPENDENT SET problem of size \( k \) on graphs of \( n \) vertices, and produce an instance of what is called the PERFECT CODE problem [16, 17] with parameter \( k^2 \) on graphs containing \( n^2 \) vertices. Then, the authors obtain a more “robust” version of Perfect Code, with certain properties of every dominating set in the instance. The new instance has parameter \( k^3 \) and the corresponding graphs contain at least \( n^3 \) vertices, and is used to derive hardness results for coding-theoretic problems. This last step is Theorem 1 in [18] and is complicated, the proof introducing a number of gadgets and spanning about eight pages. Due to the chain of reductions, this implies that the lower bound obtained for MAXIMUM LIKELIHOOD DECODING and WEIGHT DISTRIBUTION is at best \( r^{\Theta(k)} \), and this only holds if the number \( r \) of input vectors is at most linear in the dimension \( n \). Thus, their lower bound leaves open the possibility of algorithms that solve these problems in time significantly faster than testing all \( k \) subsets of \( r \) vectors. In contrast, if \( r^k < 2^n \), then our \( \min(r^{\Theta(k)}, 2^{\Theta(n)}) \) lower bound shows one cannot do polynomially better than this testing algorithm.

Once \( r^k > 2^n \), we provide a much faster algorithm based on the Fast Fourier Transform (FFT). Even when \( r^k < 2^n \), we still achieve a polynomially better algorithm than the testing algorithm. In this case our algorithm’s complexity is \( 2^{O(k)}(\frac{r^k}{k^{2/3}})\)poly(n).

For the \((k, r)\)-MINL INDEPENDENCE problem, our \( \min(r^{\Theta(k)}, 2^{\Theta(n)}) \) lower bound continues to hold provided that the characteristic of \( F_q \) does not divide \( k \). Here we give a deterministic algorithm that runs in \( 2^{O(k^2+n)} \) time. We leave it as an open question whether this can be reduced to \( 2^{O(k+n)} \) time.

1.2 Techniques and Comparison to Previous Work

1.2.1 Lower Bounds

Our starting point for the lower bound is the recent \( N^{\Omega(k)} \) bound for the \( k \)-SUM problem on \( N \) integers of [41]. We briefly review their proof in order to compare it to ours.

At the heart of their reduction is a way of creating integers \( \zeta_1, \ldots, \zeta_N \) from partial assignments \( A_1, \ldots, A_N \) to variables of a ONE-IN-THREE-SAT formula \( F \), i.e., \( F \) is a formula that evaluates to true iff exactly one literal per clause evaluates to true. This is done in such a way that there is a sum \( \zeta_i + \cdots + \zeta_k = M \) iff the partial assignments \( A_{i_1}, \ldots, A_{i_k} \) corresponding to these integers can be patched together to form a consistent assignment to all variables that causes \( F \) to evaluate to true. Here, \( M \) is the positive integer that, when written in base \( k + 1 \), equals \( 1^{k+c} \), where \( c \) is the number of clauses. The idea is to partition the \( n \) variables arbitrarily into \( k \) equal-sized groups \( G_i \). For each \( G_i \), the reduction generates a new integer \( \zeta_j \) for each assignment to the variables in that group. The \( \zeta_j \) are interpreted in base \( k + 1 \). The first \( k \) digits of each \( \zeta_j \) are set so that the \( i \)-th digit is 1 if \( \zeta_j \) comes from the \( i \)-th block, otherwise it is 0. The digit of \( \zeta_j \) corresponding to a clause is 1 if the assignment of the variables corresponding to \( \zeta_j \) causes exactly one of the literals of the clause to be true. In order to obtain a sum \( \zeta_{i_1} + \cdots + \zeta_{i_k} = M \), one must take an integer associated with each block, so
one obtains a consistent assignment, and each clause must have exactly one literal set to true.

By replacing “digits” with “coordinates” and “integers” with “vectors”, the proof of [41] shows a \( \min(2^{\Theta(n)}, \ell(n^k)) \) hardness for \((k, r)\)-ZERO\(\text{SUM}_q\) and \((k, r)\)-TARGET\(\text{SUM}_q\) with the following restrictions:

1. the characteristic of the field \( \mathbb{F}_q \) must be larger than \( k \), and
2. \( r \) belongs to a geometric sequence of numbers, rather than being an arbitrary integer.

We are not able to modify the proof of [41] to remove these restrictions. The issue is that when the characteristic is 2, there are cancellations that lead to false positives in the reduction of [41]. Indeed, trying to adapt their reduction to binary fields would instead require hardness of the problem ODD-SAT, the problem of having an odd number of literals evaluate to true in each clause. However, this latter problem is in \( \mathsf{P} \) via Gaussian elimination.

We instead base our reduction on the NOT-ALL-EQUAL-SAT problem, the problem of having one or two out of three literals evaluate to true in each clause. We again partition the variables into blocks, but now we want a clause coordinate to be 1 iff one or two of its literals evaluates to one. The obstacle, though, is that for a given block, not all the variables associated with a clause may be assigned to that block. For instance, a clause on three variables may have its variables assigned in three different blocks. It is easy to see that some interaction between the blocks is needed to enforce consistency. By using a version of NOT-ALL-EQUAL-SAT in which each variable occurs a bounded number of times, we are able to introduce a linear number of new variables and dimensions, which overall have the effect of allowing the blocks to communicate in a way that a consistent assignment is enforced.

This approach allows us to conclude hardness for a sequence \( r_0 < r_1 < r_2 < \cdots \) of values to \( r \). We show that if there were an \( r \) between \( r_1-1 \) and \( r_1 \) for which the problem were “easy”, this would contradict the hardness of the problem on \( r_1 \) vectors. This does not follow from standard “padding arguments”, since we must have distinct vectors and cannot create new dependences.

It is worth pointing out again that our bounds apply for the full range of \( r \) and \( k \), in contrast to previous work.

### 1.2.2 Upper Bounds

Our algorithms for

- \((k, r)\)-ZERO\(\text{SUM}_q\),
- \((k, r)\)-TARGET\(\text{SUM}_q\),
- \((k, r, v)\)-ZERO\(\text{SUM}_q\),
- \((k, r)\)-LINDEPENDENCE\(q\),
- \((k, r)\)-TARGET\(\text{SUM}_q\), and
- \((k, r)\)-MINLINDEPENDENCE\(q\)

problems are based on the FFT and convolution.

Our algorithm for \((k, r)\)-MINLINDEPENDENCE\(q\) is one step beyond this. We choose a small (in fact, pairwise independent) family of linear maps from \( \mathbb{F}_q^n \) to \( \mathbb{F}_q^s \) such that for any minimal \( k \)-dependence \( x_1, \ldots, x_n \) in the input, there exists a linear map \( h \) in our family for which the image of \( x_1, \ldots, x_n \) under \( h \) is a minimal \( k \)-dependence. We can find such a minimal \( k \)-dependence by testing all minimally \( k \)-dependent vectors in \( \mathbb{F}_q^s \), each test using several applications of the FFT. The small set of functions can be chosen in a variety of ways. The overall technique of hashing followed by fast convolution bears a strong similarity to the color-coding method of Alon, Yuster and Zwick [3] which applies hashing followed by fast matrix multiplication in order to find copies of a small subgraph inside a given graph.

### 2 Preliminaries

The following standard claim is useful.

**Claim 5** Let \( q > 2 \) be a prime power and let \( x_1, \ldots, x_n \) be \( n \) elements chosen independently and uniformly at random from \( \mathbb{F}_q^n \), then the probability that they are linearly independent is at least \( e^{-\frac{n}{q}} \). Equivalently, a random \( n \) by \( n \) matrix over \( \mathbb{F}_q \) is non-singular with probability at least \( e^{-\frac{n}{q}} \).

Our upper bounds depend on efficient algorithms that compute the Fourier coefficients over any abelian group. Fast Fourier Transform (FFT) algorithms first appeared in [14] for the cyclic group \( \mathbb{Z}/n\mathbb{Z} \) and later were generalized to any abelian groups (see, e.g., the survey article [37]).

**Fact 6 (Fast Fourier Transform)** Let \( \mathbb{F}_q \) be the finite field with \( q \) elements. Let \( f : \mathbb{F}_q^n \to \mathbb{C} \) be a complex-valued function defined over \( \mathbb{F}_q^n \). Then there is a Fast Fourier Transform (FFT) algorithm which compute all the Fourier coefficients of \( f \) in time \( O(nq^n) \).

**Fact 7** Let \( f_1, \ldots, f_k : \mathbb{F}_q^n \to \{0, 1\} \) be \( k \) Boolean functions defined on \( \mathbb{F}_q^n \) then the number of elements \( (x_1, \ldots, x_k) \) such that \( x_1 + \cdots + x_k = 0 \) and \( f_1(x_1) = \cdots f_k(x_k) = 1 \) can be computed from the Fourier coeffi-
cient of the convolution of these \( k \) functions:

\[
|\{ (x_1, \ldots, x_k) : x_1 + \cdots + x_k = 0 \}
\]

and \( f_i(x_i) = 1 \) for each \( i = 1, \ldots, k \} = q^{n(k-1)}(f_1 * f_2 * \cdots * f_k)(0)

\[
= q^{n(k-1)} \sum_{\alpha \in \mathbb{F}_q} \prod_{j=1}^k f_j(\alpha).
\]

(1)

3 Hardness

**Theorem 8** Given function \( k : \mathbb{Z}^+ \to \mathbb{Z}^+ \) such that \( k(n) < n \) for all \( n \in \mathbb{Z}^+ \) and function \( r : \mathbb{Z}^+ \to \mathbb{Z}^+ \) such that \( k(n) < r(n) < q^n \) for all \( n \in \mathbb{Z}^+ \), then the \((k, r)\)-\textsc{TARGETSum}_\( q \) problem requires at least

\[
\min \left( \left( \frac{r(n)}{g(k(n))}, \frac{2^{dn}}{k}\right) \right) \text{ time for some constant } \beta < 1, \text{ unless}
\]

d-\textsc{SAT} on \( n \) variables can be solved in \( 2^{O((dn)^{1/\beta}(1/d))} \) time for any \( d \geq 3 \).

**Proof** Suppose \( q \) is a power of some prime \( p \geq 2 \).

Let \( F \) be an instance of \( d\text{-}\textsc{SAT} \) with \( n \) variables and \( m \) clauses.

For some \( \epsilon > 0 \) to be specified later, we use the improved Sparsification Lemma of Calabro, Impagliazzo and Paturi [9] to reduce \( F \) to a collection of \( 2^m \) \( d\text{-}\textsc{SAT} \) formulas, with each formula having \( n \) variables and \( n \cdot (d/\epsilon)^{O(d)} \) clauses. Next, we use a standard reduction to convert each \( d\text{-}\textsc{SAT} \) formula to a 3-SAT formula with \( f \triangleq O((nd)^{1/\beta}(1/d)) \)

variables and clauses.

Now, we convert each 3-SAT formula to an \textsc{NAE-SAT} formula by a standard reduction: each clause \((v_1 \lor v_2 \lor v_3)\) is replaced by three clauses \((v_1 \lor v_2 \lor \neg x) \land (\neg x \lor v_3 \lor y) \land (x \lor y \lor \alpha)\) where \( x \) and \( y \) are new variables and \( \alpha \) is a common variable used across the clauses in the formula. Furthermore, we can ensure that each variable occurs only a constant number of times in each \textsc{NAE-SAT} formula by replacing duplicate copies of a variable by distinct variables and introducing equality constraints (two variables \( x \) and \( y \) can be constrained to be equal by two \textsc{NAE-SAT} clauses \((\neg x \lor y) \land (x \lor \neg y))\). The number of variables and clauses in each formula remains \( O(f) \).

Next, we reduce each \textsc{NAE-SAT} formula to a separate \((k, r_k)\)-\textsc{TARGETSum}_\( q \) problem, where the function \( r_k : \mathbb{Z}^+ \to \mathbb{Z}^+ \) will be specified later. Fix an arbitrary ordering of the literals inside each clause of the formula. For any literal \( \ell \), let us denote by \( v(\ell) \) the variable corresponding to the literal. To start off the reduction, for each clause \((\ell_1 \lor \ell_2 \lor \ell_3)\) in the \textsc{NAE-SAT} formula, where \( \ell_1, \ell_2, \ell_3 \) are literals, we introduce three, possibly new, variables \((v(\ell_1), v(\ell_2), v(\ell_3))\) and \((v(\ell_3), v(\ell_1))\). We call each such variable \((a, b)\) a pairvar. The number of pairvars is at most three times the number of clauses, \( O(f) \). Next, for a function \( k' : \mathbb{Z}^+ \to \mathbb{Z}^+ \) to be specified later, partition the original set of variables arbitrarily into \( k' = k'(n) \) blocks, of sizes within a constant factor of each other, and assign an arbitrary ordering among the blocks. For each pairvar \((a, b)\), if both \( a \) and \( b \) belong to the same block, we include the pairvar in that block. Otherwise, we include it in the first block containing either \( a \) or \( b \). Thus, each variable (original or pairvar) is contained in exactly one block. Also, since each variable occurs a constant number of times, each block contains \( O(f/k') \) original and pairvar variables.

We now generate the \((k, r_k)\)-\textsc{TARGETSum}_\( q \) instance. Each block will yield \( 2^{O(f/k')} \) many elements of \( \mathbb{F}_q^{n'} \), where \( n' \) will be \( O(f) \). Consider the \( i \)th block, with \( i \in [k'] \). Let \( A_i \) be the set of all possible \( 0/1 \)-assignments to the set of variables \( \{ x \mid x \text{ is an original variable in block } i \} \cup \{ a \mid \exists \text{ pairvar } (a, b) \text{ or } (b, a), \text{ not necessarily in block } i, \text{ with } b \text{ in block } i \} \). Note that an assignment in \( A_i \) fixes the values of all pairvars in block \( i \). For each assignment \( \alpha \in A_i \), we produce an element \( x_\alpha \in \mathbb{F}_q^{n'} \) in the following way. The first \( k' \) bits of \( x_\alpha \) are 0, except for the \( i \)th which is 1. Next, there is a coordinate for each clause \( C \) of the formula, called the clause coordinate. If \( C = (\ell_1 \lor \ell_2 \lor \ell_3) \), its clause coordinate value is set to:

\[
\sum_{i \in [3]: v(\ell_i) \text{ in block } i} \alpha(\ell_i) \mod p
\]

\[
- \sum_{(i,j) \in [3]^2: (v(\ell_i), v(\ell_j)) \text{ in block } i} \alpha(\ell_i)\alpha(\ell_j) \mod p.
\]

The rest of the coordinates, called the consistency coordinates, will be set so as to ensure consistency among assignments to the pairvars by different blocks. We partition the consistency coordinates into pairs and index each pair with a pairvar. For the pair of coordinates indexed by pairvar \((a, b)\), if neither \( a \) nor \( b \) is in block \( i \), then both these coordinates are set to 0, and the same if both \( a \) and \( b \) are in block \( i \). Otherwise, if \( a \) is in block \( i \) but \( b \) is not, then the first coordinate is set to \(-\alpha(a)\) and the second to \(-\alpha(b)\), and similarly, if \( a \) is not in block \( i \) but \( b \) is, then the first coordinate is set to \(-\alpha(a)\) and the second to \(\alpha(b)\). This completes the description of \( x_\alpha \). The target vector \( z \) for the \((k, r)\)-\textsc{TARGETSum}_\( q \) instance is set to \( 1^{n'-2p} \odot 0^p \) where \( p \) is the total number of pairvars. To make \( n' \) independent of \( k' \), we can pad all the strings with extra zeroes at the end.

In the above construction, we define functions \( k' \) and \( r_k \) such that \( k'(n) = k(n') \) and \( r_k(n') = \sum_{i \in [k'(n)]} |A_i| \) for every \( n \geq 1 \), where \( n' \) and the \( A_i \)’s are as above. Thus, we obtain a valid \((k, r_k)\)-\textsc{TARGETSum}_\( q \) instance, where
\( r_k(n) = k(n) \cdot 2^{O(n/k(n))} \). To see the correctness of the reduction, suppose there are \( x_{a_1}, \ldots, x_{a_i} \) such that \( x_{a_1} + \cdots + x_{a_i} = z \). First, assume that all the pairs are assigned consistently by the assignments \( \alpha_1, \ldots, \alpha_k \). Because each \( x_{a_i} \) has a 1 in only one of the first \( k' \) coordinates, and \( z \) has 1’s on all the first \( k' \) coordinates, each \( \alpha_i \) is in \( A_i \) without loss of generality. Since consistency of the pair assignments is assumed, the partial assignments \( \alpha_i \) can be combined to obtain an assignment \( \alpha \) to all the original variables. The claim is that \( \alpha \) is a satisfying assignment to the NAE-SAT formula. Take a clause \( C = (\ell_1 \lor \ell_2 \lor \ell_3) \) from the NAE-SAT formula. If we add up modulo \( p \), the value of the clause coordinate corresponding to \( C \) for each \( x_{a_i} \), then this sum must equal:

\[
S_C = (\alpha(\ell_1) + \alpha(\ell_2) + \alpha(\ell_3) - \alpha(\ell_1)\alpha(\ell_2) - \alpha(\ell_2)\alpha(\ell_3) - \alpha(\ell_3)\alpha(\ell_1)) \mod p
\]

- If three literals in \( C \) are assigned 1, then \( S_C = 1 + 1 + 1 = 3 \).
- If two literals in \( C \) are assigned 1, then \( S_C = 1 + 1 + 1 = 3 \).
- If one literal in \( C \) is assigned 1, then \( S_C = 1 + 0 + 0 = 1 \).
- If no literal in \( C \) is assigned 1, then \( S_C = 0 + 0 + 0 = 0 \).

Since all the clause coordinates of \( z \) are set to 1, it must be the case that \( \alpha \) satisfies the NAE-SAT formula.

It remains to check that the pair variables are set consistently. For the pair of consistency coordinates indexed by a pair \((a, b)\), either these coordinates are zero in all of the \( x_{a_i} \)'s, or there exist \( i \neq j \) such that these coordinates are nonzero in \( x_{a_i} \) and \( x_{a_j} \), but they are zero for all the other strings. In the first case, there is no consistency issue. The second case occurs when one of \( a \) and \( b \) is in block \( i \) and the other is in block \( j \). But then, because the value of \( x_{a_i} + x_{a_j} \) is zero at the consistency coordinates indexed by \((a, b)\), it must be the case that \( \alpha_i(a) - \alpha_j(a) = 0 \) and \( \alpha_i(b) - \alpha_j(b) = 0 \).

Thus, the reduction yields \( 2^{n'k'}(k, r_k)\)-TARGETSUM\(_q\) instances on \( n' = O(dn)(d/e)^{O(d)} \) many coordinates, with \( r_k(n') = k' \cdot 2^{O(f/k')} = k' \cdot 2^{O(d/e)(d/e)k'} = k' \cdot 2^{O(d/e)(d/e)} \), where the last equality follows by choosing \( \epsilon = d\delta^{1/\gamma} \) for an appropriate value of \( \gamma \). Therefore, if the output of the reduction can be solved in time \((r_k(n'))^{1/\delta_k(n')}\), then, using the standard bound \( (r_k(n'))^{1/\delta_k(n')} \leq ae^{b'c}b'\), an arbitrary \( d\)-SAT on \( n \) variables can be solved in time

\[
2^{n} \cdot (e/\delta)^{2^{O(d/e)(d/e)}} \cdot 2^{O(dn)\delta^{1/\gamma}}.
\]

We need to show how to reduce a \((k, r_k)\)-TARGETSUM\(_q\) to a \((k, r)\)-TARGETSUM\(_q\) instance for an arbitrary function \( r : \mathbb{Z}^+ \to \mathbb{Z}^+ \). First consider the case of \( r(n) \leq r_k(n) \). For \( i \in \mathbb{Z}[n/k(n)] \), let \( k_i : \mathbb{Z}^+ \to \mathbb{Z}^+ \) be defined so that \( k_i(n) = n/i \). Note that \( k_i(n) < n \) if \( k(n) < n \) for all positive \( i \).

Now, apply the reduction above to get an instance of \((k_i, r_k)\)-TARGETSUM\(_q\) of size \( ik(n) \) that requires \((r_{ik}(n))^{1/\delta_k(n)}\) time, unless \( d\)-SAT on \( n \) variables can be solved in \( 2^{O(dn)\delta^{1/\gamma}} \) time. We can pad the strings of such an instance with zeroes in order to get an instance of \((k, r)\)-TARGETSUM\(_q\) of size \( n \) with the same hardness guarantee, where \( r_i(n) = r_k(ik(n)) = k(n) \cdot 2^{O(i)} \). Now, for the given \( r \), suppose \( r_i(n) < r(n) < r_{i+1}(n) \) for some \( i \in \mathbb{Z}[n/k(n)] \). We show how to reduce \((k, r_{i+1})\)-TARGETSUM\(_q\) to \((k, r)\)-TARGETSUM\(_q\). We need the following claim.

**Claim 9** For positive integers \( k < m < n \), there exists a collection \( C \) of subsets of \([n]\) such that each subset \( S \in C \) is of size \( m \) and for any subset \( I \subset [n] \) of size \( k \), there exists \( S \subset C \) containing \( I \). The size of \( C \) is at most \((12n/m)^k \), and it can be constructed deterministically in the same amount of time.

**Proof** Arbitrarily partition \([n]\) into nearly equal-sized buckets, each of size either \( \lceil m/2k \rceil \) or \( \lfloor m/2k \rfloor \). The number of buckets is at most \( 4nk/m \). Consider all subsets of exactly \( k \) of these buckets. There are \((4nk/m)^k \leq (4en/m)^k\) many such subsets. For each choice of \( k \) buckets, take the union \( S \) of items in these buckets. \( S \) contains at most \( m/2 < m \) items; add \( m - |S| \) many arbitrary distinct additional items to \( S \) so as to make the size of \( S \) equal to \( m \). The collection of all \( S \) satisfies our claim.

Apply Claim 9 with \( k \) as above, \( m = r \), \( n = r_{i+1} \). The size of the collection \( C \) we get is \( 2^{O(k)} \). Now, suppose there is an algorithm \( A_r \) for \((k, r)\)-TARGETSUM\(_q\). Given \( x_1, \ldots, x_{r_{i+1}} \) and a target vector \( z \), for every \( S \subset C \), run \( A_r \) with input \([x_i : i \in S]\) and the same target vector \( z \). If indeed there exists a solution of \((k, r_{i+1})\)-TARGETSUM\(_q\), \( A_r \) should accept for some choice of \( S \subset C \). Hence, if \( A_r \) runs in time \( 2^{O(k)} \), then \((r_{i+1})^{1/\delta_k(ik(n))} \leq (r_{i+1})^{1/\delta_k(ik(n))} \), implying there is an algorithm for \( d\)-SAT running in time \( 2^{O(dn)\delta^{1/\gamma}} \).

It remains to consider the case of \( r(n) > r_k(n) \). Define \( \ell : \mathbb{Z}^+ \to \mathbb{Z}^+ \) so that \( r(n) - k(n) = r(n) - k(n) \) for every \( n \geq 1 \). First, obtain a hard instance \((\ell, r)\)-TARGETSUM\(_q\) of size \( n - k \) by the earlier reduction. The instance consists of \( r(n) - k(n) \) vectors \( x_1, \ldots, x_{r - k} \in \mathbb{F}_q^{k' - k} \) and a target vector \( z \in \mathbb{F}_q^{k'} \), and say \( x_1, \ldots, x_s \) for some \( s < r - k \) consists of the vectors that arise out of assignments to the first block in
the reduction from $d$-SAT. We construct an instance of $(k, r)$-$\text{TARGETSUM}_q$ of size $n$, consisting of $y_1, \ldots, y_t \in \mathbb{F}_q^n$ and target vector $w \in \mathbb{F}_q^n$. Set $w$ to $z \circ 0^q$. For $i \in [k]$, set $y_{r-k+1}$ to $0^i \circ e_i$, where $e_i \in \mathbb{F}_q^k$ has all $0$’s except for $1$ at the $i$th position. For $i \in [s + 1, r - k]$, set $y_i = x_i \circ 0^s$. Finally, for $i \in [s]$, set $y_i = x_i \circ v$, where $v \in \mathbb{F}_q^k$ is the vector with $-1$’s in the first $k - \ell$ positions and $0$’s in the rest. Observe that any solution to this $(k, r)$-$\text{TARGETSUM}_q$ instance, when restricted to the first $r - k$ coordinates, must yield a solution to the $(\ell, r)$-$\text{TARGETSUM}_q$ instance, and so in particular, must contain one of $y_1, \ldots, y_s$. But then, to satisfy the constraints on the last $k$ coordinates, the solution must also contain $\{y_{r-k+1}, \ldots, y_{r-\ell}\}$. This gives a correspondence between solutions to the $(\ell, r)$-$\text{TARGETSUM}_q$ instance and the $(k, r)$-$\text{TARGETSUM}_q$ instance. Hence, unless there is an algorithm to solve $d$-SAT in $2^{O(dn^{3/2}k)}$ time, solving $(r, k)$-$\text{TARGETSUM}_q$ requires at least $2^{\beta(n/2)} = 2^{\beta n}$ time for some constant $\beta < 1$. \[ \square \]

Now, consider the $(k, r, v)$-$\text{TARGETSUM}_q$ problem, where $k$ and $r$ are as in Theorem 8 and $v$ denotes an arbitrary family of vectors in $(\mathbb{F}_q \setminus \{0\})^n$. We observe that the above proof of Theorem 8 also shows hardness for this problem. Specifically, in the reduction from NAE-SAT, multiply each vector arising from block $i$ by $v_i^{-1}$, for every $i \in [k'(n)]$. It is easy to see that this gives a reduction from NAE-SAT to $(k, r, v)$-$\text{TARGETSUM}_q$ for the same function $r_k$ as in the above proof. The rest of the proof goes through straightforwardly, with the only other nontrivial modification occurring in the last paragraph of the proof where we again need to multiply the vectors being appended by the appropriate scaling factors. We have thus proved the following.

**Theorem 10** Given $k, r : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ as in Theorem 8 and an arbitrary family of vectors $v = (v_1, \ldots, v_{k(n)}) \in (\mathbb{F}_q \setminus \{0\})^{k(n)}$ for every $n \geq 1$, the $(k, r, v)$-$\text{TARGETSUM}_q$ problem requires at least $\min \left( \left( \beta k(n) \right)^{d/2}, 2^{\beta n} \right)$ time for some constant $\beta < 1$, unless $d$-SAT on $n$ variables can be solved in $2^{O(dn^{3/2}k)}$ time for any $d \geq 3$.

For the $(k, r, v)$-$\text{ZERO SUM}_q$ problem, we have already observed that the problem is trivial if $s_v = \sum y_{i(v)} v_i = 0$ over $\mathbb{F}_q$. But if $s_v \neq 0$, then we can again show the same hardness as above by reducing from $(k, r, v)$-$\text{TARGETSUM}_q$. Given $x_1, \ldots, x_t$ and target vector $z$, define $y_i = x_i - s_v^{-1} z$ for every $i \in [r]$. Now, if the instance of $(k, r, v)$-$\text{ZERO SUM}_q$ with inputs $y_1, \ldots, y_t$ has a solution $i_1, \ldots, i_k \in [r]$ such that $\sum_{i=1}^k v_i y_i = 0$, then $\sum_{i=1}^k v_i x_i = z$ and vice versa. Therefore:

**Theorem 11** Given $k, r : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ as in Theorem 8 and a family of vectors $v = (v_1, \ldots, v_{k(n)}) \in (\mathbb{F}_q \setminus \{0\})^{k(n)}$ such that $\sum_{i=1}^k v_i \neq 0$ for every $n \geq 1$, the $(k, r, v)$-$\text{ZERO SUM}_q$ problem requires at least $\min \left( \left( \beta k(n) \right)^{d/2}, 2^{\beta n} \right)$ time for some constant $\beta < 1$, unless $d$-SAT on $n$ variables can be solved in $2^{O(dn^{3/2}k)}$ time for any $d \geq 3$.

Specifically, this hardness holds for the $(k, r)$-$\text{ZERO SUM}_q$ problem if $k(n) \neq 0 \pmod{p}$ where $p$ is the characteristic of $\mathbb{F}_q$.

For the $(k, r)$-$\text{LINDEPENDENCE}_q$ problem also, we can show the same hardness, this time by examining the proof of Theorem 8. Observe that for the output of the reduction from the NAE-SAT instance in the proof, not only is the generated target vector the sum of $k'$ vectors iff the NAE-SAT formula is satisfiable but actually, the generated target vector is in the span of $k'$ vectors iff the NAE-SAT formula is satisfiable. The rest of the proof goes through straightforwardly.

**Theorem 12** Given $k, r : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ as in Theorem 8, the $(k, r)$-$\text{LINDEPENDENCE}_q$ problem requires at least $\min \left( \left( \beta k(n) \right)^{d/2}, 2^{\beta n} \right)$ time for some constant $\beta < 1$, unless $d$-SAT on $n$ variables can be solved in $2^{O(dn^{3/2}k)}$ time for any $d \geq 3$.

### 4 Algorithms for $(k, r, v)$-$\text{TARGETSUM}_q$ and $(k, r)$-$\text{LINDEPENDENCE}_q$

We show how to solve the $(k, r, v)$-$\text{TARGETSUM}_q$ problem in $2^{O(k)} \left( \binom{r}{k/2} \cdot \text{poly}(n) \right)$ time for constant $q$, which improves the $\left( \binom{r}{k} \right) \cdot \text{poly}(n)$ time algorithm of exhaustive search. This implies a solution for $(k, r)$-$\text{TARGETSUM}_q, (k, r)$-$\text{ZERO SUM}_q,$ and $(k, r)$-$\text{LINDEPENDENCE}_q$. By enumerating over different $v$, it can also be used to solve $(k, r)$-$\text{LINDEPENDENCE}_q$ with a blowup of an additional $q^k$ factor.

The basic idea is most easily seen for the $(k, r)$-$\text{TARGETSUM}_q$ problem. In this case $v = 1^k$. We form a table $T$ of all possible vector sums of $k/2$ vectors $x_{11}, \ldots, x_{k/2}$ from $x_1, x_2, \ldots, x_r$. Next, for each vector $w \in T$, we check if $w \oplus z \in T$, where $z \in \mathbb{F}_q^n$ is the target vector. Since we do not require that $i_1, i_2, \ldots, i_k$ are distinct, if there is a sum of $k$ input vectors that equals $z$, we will find it, and if we find such a sum, it solves the $(k, r, v)$-$\text{TARGETSUM}_2$ problem. The time is clearly $\left( \binom{r}{k/2} \right) \cdot \text{poly}(n)$. Handling odd $k$ is straightforward - we can build a table $T_1$ of all sums of $[k/2]$ input vectors, and a table $T_2$ of all sums of $[k/2]$ input vectors, and check if there is a vector $w \in T_1$ for which $w \oplus z \in T_2$, which can be done in $\left( |T_1| + |T_2| \right) \cdot \text{poly}(n)$ time.

7
We now describe the extension for general $q$. The main difference is that we first group the coefficients of $v = (v_1, \ldots, v_k)$ based on their value in $F_q \setminus \{0\}$. Let $z \in F_q^n$ be the target vector. Let the input vectors be $x_1, \ldots, x_r \in F_q^n$, so we want to find a sub-multiset $x_{i_1}, \ldots, x_{i_k}$ for which $\sum_{j=1}^k v_j x_{i_j} = z$.

In the first stage, for each subset $A$ of the input vectors of size $\lceil k/2 \rceil$, the algorithm considers a special set of $2^O(k)$ sequences $(x_{i_1}, \ldots, x_{i_{\lceil k/2 \rceil}})$ of $\lceil k/2 \rceil$ elements of $A$ with repetition. Here, some elements of $A$ may not be included in a given sequence in the set.

The special set of sequences for the subset $A$ is formed as follows. For a sequence $(x_{i_1}, \ldots, x_{i_{\lceil k/2 \rceil}})$ of $\lceil k/2 \rceil$ elements of $A$ (with repetition), for each $\ell \in F_q \setminus \{0\}$, let $B_\ell$ be the multiset of $x_{i_j}$ for which $v_j = \ell$. Note that $|B_\ell|$ is the number of coordinates of $v$ which equal $\ell$. Let $C_\ell$ be the multiset obtained from $B_\ell$ by taking each distinct element of $B_\ell$, and reducing its multiplicity modulo the characteristic of $F_q$. For any two sequences $(x_{i_1}, \ldots, x_{i_{\lceil k/2 \rceil}})$ and $(y_{i_1}, \ldots, y_{i_{\lceil k/2 \rceil}})$ which result in the same collection of multisets $\{C_\ell\}$, we have $\sum_{j=1}^{\lceil k/2 \rceil} v_j x_{i_j} = \sum_{j=1}^{\lceil k/2 \rceil} v_j y_{i_j}$. In this case we say sequences $(x_{i_1}, \ldots, x_{i_{\lceil k/2 \rceil}})$ and $(y_{i_1}, \ldots, y_{i_{\lceil k/2 \rceil}})$ are equivalent.

The special set of sequences we use for the subset $A$ is a maximal set of non-equivalent sequences, and we call such a set of sequences a representative sequence set. The number of sequences in the representative sequence set is bounded by $2^O(k)$ for constant $q$. To see this, for each distinct element $x$ of $A$, and for each of the at most $q - 1$ different $C_\ell$, we choose a number between 0 and the characteristic of $F_q$, minus one, which is at most $q$ representing the number of occurrences of $x$ in $C_\ell$. Since $A$ has at most $\lceil k/2 \rceil$ distinct elements, the number of choices we have is $q^{O(qk)} = 2^O(k)$ for constant $q$. However, not all such collections of $\{C_\ell\}$ correspond to a sequence of exactly $\lceil k/2 \rceil$ elements of $A$. For each such collection of $\{C_\ell\}$, there is such a sequence if and only if $|B_\ell| - |C_\ell|$ is a multiple of the characteristic of $F_q$ for all $\ell$. Indeed, in this case, case we can arbitrarily increase the multiplicity of a vector in $C_\ell$ by a multiple of the characteristic. On the other hand, any sequence gives rise to a collection $\{C_\ell\}$ with the property that $|B_\ell| - |C_\ell|$ is a multiple of the characteristic of $F_q$ for all $\ell$. For each sequence in the representative sequence set, the algorithm first computes the vector $\sum_{j=1}^{\lceil k/2 \rceil} v_j x_{i_j}$. This can be done in $2^O(k) \cdot r$ time.

In the second stage, for each sub-multiset $B$ of the input vectors of size $\lceil k/2 \rceil$, the algorithm considers all sequences $(x_{i_1}, \ldots, x_{i_{\lceil k/2 \rceil}})$ of $B$ from a representative sequence set, and computes $\sum_{j=1}^{\lceil k/2 \rceil} v_j [\lceil k/2 \rceil] x_{i_j}$.

Then there is a solution to the $(k, q, v)$-TARGETSUM problem if and only if there is a vector $w$ computed in the first stage for which the vector $-w + z$ is computed in the second stage. This can be easily tested in $2^O(k) \cdot r \cdot poly(n)$ time. We thus have:

**Theorem 13** $(k, r, v)$-TARGETSUM$_q$ can be solved in deterministic $2^O(k) \cdot r \cdot poly(n)$ time.

When $r = 2^O(n/k)$, we can do better and match the lower bound from Theorem 8, up to a constant factor in the exponent. Again, suppose we have an instance of $(k, r, v)$-TARGETSUM$_q$ with inputs $x_1, \ldots, x_r \in F_q^n$ and target vector $z \in F_q^n$. For $i \in [k]$, define the set $S_i \subseteq F_q^n$ to be $\{v_i x_j \mid j \in [r]\}$, and let $f_i : F_q^n \rightarrow \{0, 1\}$ be the indicator function of $S_i$. Now, Fact 7, concerning convolution and the FFT, directly leads to:

**Theorem 14** $(k, r, v)$-TARGETSUM$_q$ can be solved in deterministic $O(n \cdot \log k(n) \cdot q^n)$ time.

5 $(k, r)$-MINLINDEPENDENCE$_q$ Algorithms and Algorithms for Related Problems

5.1 An algorithm for the decision problem

In this section, we show an algorithm for the $(k, r)$-MINLINDEPENDENCE$_q$ problem which is tight for $k(n) = O(\sqrt{n})$ but is not for larger $k$.

**Theorem 15** For functions $k, r : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$, the $(k, r)$-MINLINDEPENDENCE$_q$ problem can be solved in $O \left( \text{poly}(n) \cdot \min \left( \frac{r(n)}{k(n)}, q^{O(n+k^2(n))} \right) \right)$ deterministic time.

**Proof** The algorithm with running time $\text{poly}(n)(r(n))$ simply picks each $k(n)$-sized subset of the $r(n)$ inputs and checks if they are minimally dependent using Gaussian elimination. For the other upper bound, we first give a randomized algorithm which is easy to describe, and for which there is a standard way to derandomize it.

Choose uniformly at random a full-rank linear map $L : F_q^n \rightarrow F_q^{k-1}$. The algorithm passes if and only if there are $x_{i_1}, \ldots, x_{i_k}$ for $i_1, \ldots, i_k \in [r]$ such that: (i) $L(x_{i_1}), \ldots, L(x_{i_{k-1}})$ are linearly independent, and (ii) $x_{i_k} \in \text{span}(x_{i_1}, \ldots, x_{i_{k-1}})$. We need to justify the success probability of this algorithm as well as its running time.

Suppose there is no subset of $k$ minimally dependent elements. In this case, note that if $L(x_{i_1}), \ldots, L(x_{i_{k-1}})$
are linearly independent, then \( x_{i_1}, \ldots, x_{i_{k-1}} \) are also linearly independent. Therefore, the above algorithm will fail with probability 1. On the other hand, suppose that the input contains a set of \( k \) minimally dependent elements \( x_{i_1}, \ldots, x_{i_k} \). Then, \( x_{i_1}, \ldots, x_{i_{k-1}} \) are linearly independent. Therefore, the probability that \( L(x_{i_1}), \ldots, L(x_{i_{k-1}}) \) are linearly independent is exactly equal to the probability that \( k-1 \) elements, uniformly chosen from \( \mathbb{F}_q^{k-1} \), are linearly independent. This probability is lower bounded by a constant by Claim 5, and so, the algorithm passes with constant probability. Finally, note that since the given algorithm is one-sided, we can amplify the success probability to any required threshold by running it \( O(1) \) times and passing if any of the runs passes.

We now describe how to get the claimed running time. We repeat the following for each choice of \( v_1, \ldots, v_{k-1} \in \mathbb{F}_q^n \) that are not all zero. For each choice of \( k-1 \) linearly independent elements \( y_{i_1}, \ldots, y_{i_{k-1}} \in \mathbb{F}_q^{k-1} \), with \( y_k \) defined as \( v_1 y_{i_1} + \cdots + v_k y_{i_{k-1}} \), we will show how to efficiently check if there exist any \( x_{i_1}, \ldots, x_{i_k} \) such that \( L(x_{i_1}) = y_{i_1}, \ldots, L(x_{i_k}) = y_{i_k} \) and \( x_{i_1} + \cdots + x_{i_{k-1}} = 0 \).

For each of the at most \( \binom{k}{k} \leq q^O(k^2) \) choices of \( y_1, \ldots, y_k \), we will achieve this in \( \tilde{O}(q^n \text{poly}(n)) \) time, proving our claim. So, fix linearly independent \( y_{i_1}, \ldots, y_{i_{k-1}} \in \mathbb{F}_q^{k-1} \) and set \( y_k \) to \( v_1 y_{i_1} + \cdots + v_k y_{i_{k-1}} \). Let \( H \) equal \( \ker(L) = \{ x : L(x) = 0 \} \); \( H \) is a subspace of dimension \( n-k+1 \). For each \( i \in [k] \), we have that \( L^{-1}(y_{i_j}) \) is a coset \( v_j + H \). For each \( j \in [k] \), we define \( f_j : H \to \{0, 1\} \) as \( f_j(x) = I(v_j + x) \), where \( I(x) = 1 \) if \( x \) is one of the \( r \) inputs and 0 otherwise. Now, observe that there exist \( x_{i_1} \in L^{-1}(y_{i_1}), \ldots, x_{i_k} \in L^{-1}(y_{i_k}) \) such that \( x_{i_1} + \cdots + x_{i_k} = 0 \) if and only if \( (f_1 \ast f_2 \ast \cdots \ast f_k)(0) > 0 \). By Fact 7, concerning convolution and the FFT, we can compute the convolution in \( O(q^m) \) time, proving the running time bound.

**Derandomization.** We can choose a family \( \mathcal{H} \) of pairwise-independent hash functions from \( \mathbb{F}_q^n \) to \( \mathbb{F}_q^m \) as follows. We choose \( a \in \mathbb{F}_q^n \) and \( b \in \mathbb{F}_q^m \) arbitrarily, and our map is \( [a \cdot x]_b + b \), where \([y]_b \) denotes the restriction to the last \( k \) coordinates of \( y \). Then \( |\mathcal{H}| = q^{m+3k} \). Such a family is known to be pairwise-independent. Although the family is not linear, it is affine, and we know the offset \( b \), so we can perform the above algorithm by looking for sets of \( k \) vectors in the range with the property that any non-trivial linear combination of them that spans a scalar multiple of the offset \( b \) must have a non-zero coefficient multiplying every vector, and there is such a linear combination.

Suppose that \( S \) is a set of \( k \) items that forms a linear dependence that is not minimal. Then there is a linear dependence on a proper non-empty subset of these items. It follows that a multiple of \( b \) is in the span of this subset, and so it cannot map to a set of \( k \) vectors in the range that we consider.

Suppose that \( S \) is a set of \( k \) items that is linearly independent. This set will not be found by the FFT verification, even if it passes our criterion (e.g., if we look at its image).

Suppose that \( S \) is a minimal \( k \)-dependence. With probability \( 1 - k^2/q^{3k} \), the \( k \) vectors map to distinct images. Moreover, since the map is affine, a linear combination involving all \( k \) such vectors equals a multiple of \( b \). It remains to check that any proper non-empty subset \( T \) of \( S \) does not span a multiple of \( b \). There are at most \( q^k \) elements in the union of such sets \( T \), and none can be zero since \( S \) is a minimal \( k \)-dependence. For any fixed element \( y \), the probability that \([a \cdot y]_b \) is a multiple of \( b \) is at most \( q^k/q^{3k} \), and so by a union bound none of these span a multiple of \( b \) with probability at least \( 1 - q^{k+1}/q^{3k} \). Hence, by a union bound \( S \) will pass the criteria of our procedure with probability at least \( 1 - k^2/q^{3k} - q^k/q^{3k} \).

### 5.2 An approximation algorithm for counting the number of witnesses

Note that the algorithms in Section 4 not only detect solutions to the \textsc{TargetSum} problem but also count them. It is easy to see this is the case for the first algorithm. For the second FFT-based algorithm, the output of the convolution itself gives the count. The situation is more complicated for the FFT-based algorithm for the \textsc{MinLinDependence} problem. Here, we are only able to find an approximation to the total number of solutions.

**Theorem 16** For any \( \epsilon > 0 \), there exists a randomized algorithm that, with probability at least \( 2/3 \), approximates the number of solutions to \((k, r)\)-\textsc{MinLinDependence}, to within a multiplicative factor of \((1 \pm \epsilon)\). The running time of the algorithm is \( \tilde{O}(q^{O(n+k^2)} \text{poly}(n)/\epsilon^2) \).

**Proof** The algorithm for approximate counting is essentially the same as the algorithm for detecting! As before, choose a random full-rank linear map \( L : \mathbb{F}_q^n \to \mathbb{F}_q^k \). Suppose there are \( s \) solutions to \((k, r)\)-\textsc{MinLinDependence}. By Claim 5, for each such solution \( x_{i_1}, \ldots, x_{i_k} \), the probability that \( L(x_{i_1}), \ldots, L(x_{i_{k-1}}) \) are linearly independent is at least a constant, say, \( p_k \), and so, the expected number of solutions with linearly independent \( L(x_{i_1}), \ldots, L(x_{i_{k-1}}) \) is \( sp_k \). We want to bound the concentration around this mean.
Formally, let $C$ denote the set consisting of all the $s$ solutions. For a given $c \in C$, let $\chi_c$ be the indicator variable for the event that $L$ maps $k-1$ of the elements in $c$ to linearly independent elements, and let $X = \sum_{c \in C} \chi_c$. So, $\mathbb{E}[\chi_c] = p_k$ and $\mathbb{E}[X] = sp_k$. Also, $\text{Var}[X] = \sum_{c \in C} \text{Var}[\chi_c] + \sum_{c \neq c' \in C} \text{Cov}(\chi_c, \chi_{c'})$. But note that:

$$\text{Var}[\chi_c] = p_k(1 - p_k) \leq p_k$$

and

$$\text{Cov}(\chi_c, \chi_{c'}) = \mathbb{E}[\chi_c \chi_{c'}] - \mathbb{E}[\chi_c] \mathbb{E}[\chi_{c'}] \leq \mathbb{E}[\chi_c \chi_{c'}] \leq p_k$$

So, $\text{Var}[X] \leq sp_k + s(s-1)p_k = s^2p_k$.

Now, suppose we independently choose $s$ full-rank linear maps $L_1, \ldots, L_s : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^k$, and let $Y$ be the average of the $s$ independent copies of $X$. Then, $\mathbb{E}[Y] = \mathbb{E}[X] = sp_k$, while $\text{Var}[Y] = \text{Var}[X]/s \leq s^2p_k/s$. By Chebyshev:

$$\text{Pr}[|Y - sp_k| > \epsilon sp_k] \leq \frac{\text{Var}[Y]}{\epsilon^2sp_k} \leq \frac{1}{\epsilon^2pks}$$

Thus, choosing $s$ to be $O(1/\epsilon^2)$ suffices to make the probability of error less than $2/3$.

The algorithm is therefore to independently choose $m = O(1/\epsilon^2)$ many full-rank linear maps $L_1, \ldots, L_m : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^k$, and for each $L_j$, compute $X_j$, the number of linearly dependent elements $x_{i_1}, \ldots, x_{i_k}$ such that $L_j(x_{i_1}), \ldots, L_j(x_{i_k-1})$ are linearly independent. $X_j$ is simply the approximate scaling of the value of the computed convolution. This makes the running time $O(\text{poly}(n)q^d(n+r^2)/\epsilon^2)$. Finally, we output $\sum_{i=1}^{s} X_i/sp_k$.
